FOREWORD

The monitoring and analysis of benthic invertebrates along the Canadian coastal zone of Lake Huron, Georgian Bay and the North Channel was carried out in 1980 under contract to Dr. David R. Barton of the University of Waterloo. It is the most comprehensive survey to date of the nearshore zone of any of the Great Lakes and will serve as a baseline against which other lakes and future changes in environmental conditions can be assessed.

This study, part of the Ministry's contribution to the Great Lakes International Surveillance Program (GLISP), fills a major gap in knowledge of the ecology of Lake Huron and its largest subdivisions, Georgian Bay and North Channel, with respect to the actual enumeration and identification of benthos from a wide range of bottom substrate types.

Airlift sampling employing divers rather than Ponar grabs was found to best reflect the actual population of benthos since samples were easily obtained from the wide range of often coarse sediments.

This project was undertaken as part of the Canada-Ontario Agreement on Great Lakes Water Quality and as such received federally assisted funding.

ABSTRACT

Samples of benthic invertebrates were collected during 1980 by divers from 86 stations in the nearshore zone (depths of 5-20m) of Lake Huron, Georgian Bay and North Channel. Six general categories of substratum were encountered: rock, gravel, hard clay, sand, silt/sand and silt. Abundance of invertebrates varied with depth and substratum, ranging from 456m^{-2} to 45701m^{-2} . Clay and gravel usually supported the largest populations, rock the smallest. A total of 218 taxa were recognized, including a first record of the naidid, Ripistes parasitica. With only a few exceptions, individual taxa were distributed throughout the study area. The most abundant groups were Nematoda, Oligochaeta, Mollusca and Chironomidae. Ephemeroptera and Trichoptera occurred at 83% of 5 and 10m stations. Ordination analysis failed to define distinctive communities which could be related to environmental parameters such as depth or substratum, except that a low-density assemblage of nematodes, worms and Pontoporeia was found at deep, silty stations in North Channel.

Comparison of these results with those of earlier studies illustrated the much greater efficiency achieved through direct sampling by divers. Estimates of invertebrate standing stocks were about an order of magnitude greater in the present survey and the variety of organisms was much greater since all substrata could be sampled. There was no indication of increased eutrophication or unusual environmental stress within the study area. This study is the most comprehensive survey to date of the nearshore zone of any of the Great Lakes and will serve as a baseline against which the other lakes and future changes can be compared.

INTRODUCTION

Despite the development of an extensive literature in the last two decades describing the benthic fauna of the Great Lakes, the nearshore zone has been largely neglected. This has been due to the lack of satisfactory methods for obtaining samples of benthic animals from the wide range of often coarse sediments found at depths of less than 20m. This study was undertaken as a first step toward filling this major gap in our knowledge of the ecology of Lake Huron and its largest subdivisions, Georgian Bay and North Channel. The problem of sampling was solved by employing divers rather than less versatile grabs or dredges.

This report details the results of a nearshore survey conducted in early autumn 1980. It is not a complete description of the biology of this complex and dynamic portion of the Great Lakes, but still constitutes the most detailed and comprehensive survey available to date. It is hoped that these results will prompt further studies of nearshore processes and serve as a baseline against which any future changes in the condition of Lake Huron can be assessed.

METHODS

The locations of sampling transects are shown in Figs. 1 and 2. Transects H17, G26, G27 and all North Channel stations were sampled between 24 September and 7 October 1980, by Laidlaw (1980). The remaining transects were sampled by Bio-Environmental Services, Ltd. (1981) between 19 September and 17 October 1980.

Stations were selected at depths of 5, 10 & 20m along each transect except those in shallow or narrow parts of bays (e.g. G14A, G14C, G15A, G15C, NA, NB). Divers collected 3 samples at each station. On silt or sand a plastic tube (10 cm inside diameter) was pushed by hand up to 20cm into the bottom, capped, removed from the sediment and capped on the lower end before being carried to the surface. Each core of sediment was washed through a sieve (200µm apertures) and the residue was preserved with 10% formalin. On rocky substrata samples were collected with an airlift similar to that described by Barton and Hynes (1978) equipped with a 200µm mesh collecting bag. The area sampled was defined by a section of coring tube held firmly against the bottom. These samples were also preserved immediately in 10% formalin. The divers noted the nature of the substratum at each station as proportions of rock, gravel, sand, clay or silt.

Invertebrates were sorted from the samples with the aid of a dissecting microscope by Bio-Environmental Services, Ltd. (1981). Microcrustaceans (Copepoda, Cladocera, Ostracoda) were not removed from the residues.

All animals were identified to the lowest practical taxonomic level (see Appendix A). Oligochaetes were mounted on slides in polyvinyl lactophenol and allowed to clear before being examined. In the case of a few samples which contained very large numbers of worms, a random subsample of at least 100 individuals was examined. Identification of molluscs was hampered by extensive decalcification caused by the use of unbuffered preservative.

All sample counts were $\log_{10}$ -transformed before calculating 95% confidence limits (Elliott 1977). Ordinations were performed using the University of Waterloo computer system with an ordination package (ORDIFLEX) by Gauch 1977).

RESULTS

The 218 taxa identified from the benthic collections taken during this survey are listed in Appendix A. Appendix B lists the complete contents of each sample; individual counts may be converted to individuals m^{-2} by multiplying by 127.3.

Six general types of substratum were encountered in the study area: rock (including boulders and exposed bedrock), gravel, hardclay, sand, silt/sand and silt (Table 1). Hard clay was found only at G5-20, N18-5 and N18-10. Gravel was sampled only at Lake Huron and Georgian Bay stations. Other substrata were encountered throughout the study area and at all depths.

Mean total standing stocks of invertebrates ranged from 456 m^{-2} at Station N12-20 to 45701 m^{-2} at G2-20. With the exception of uniformly low standing stocks at depths of 20m in North Channel, there were no general trends in the distribution of total abundance of invertebrates, either by region or depth (Figs. 3 & 4). This seemed to be due to the variable relationship between total numbers and substrate and depth (Table 2). Abundance was similar at all depths on gravel and decreased with increasing depth on silt. On rock and clay standing stocks were similar at 5m and 10m, but lower at 20m. Significantly more animals were collected at 10m than at 5m or 20m on sand. On silt/sand total numbers were significantly lower at 10m. Total numbers of invertebrates were extremely variable but, in general, clay and gravel supported the largest standing stocks and rock the smallest.

The mean numbers of taxa sample⁻¹ showed similar trends with depth on the different substrata (Table 3). The only difference in the general pattern was that there was no significant change in the number of taxa at different depths on sand. Hard clay supported more taxa at depths of 5m and 10m than any other substratum, although it should be emphasized that clay was sampled only at one station at each depth. The greatest variety of animals at 20m was found on silt/sand and gravel.

The five stations on Transect G16, located at depths of 1-2m on The Mary Ward Shoal, supported benthic communities which were similar to those found on the same substrata at 5m stations. Standing stocks followed the same general relationship with substrate, ranging from 1400m^{-2} on rock to an average of 23478 on gravel (Fig. 4a).

Qualitatively, the fauna of the nearshore zone was fairly homogeneous throughout Lake Huron, Georgian Bay and North Channel. The 15 stations in Lake Huron yielded a total of 126 taxa, 172 taxa were collected from 42 stations in Georgian Bay, and the 28 stations in North Channel supported 147 taxa. With only a few exceptions, animals which were found at 5 or more stations were also found in each region, i.e. common species were common throughout the study area. Noteworthy exceptions include Manayunkia speciosa and Crangonyx gracilis which were not found at any Huron station. Gammarus pseudolimnaeus and Asellus intermedius were not collected in North Channel, but Hexagenia spp. were found only there. Most larval Chironomidae were early instars which could not be assigned to species so specific distributions remain in doubt.

The species collected during this survey include a number of new records of Oligochaeta for Lake Huron. These include Peloscolex curvisetosus, Tubifex ignotus, Piquetiella michiganensis, Pristina longiseta and Ripistes parasitica. The specimens of R. parasitica found on transect NA are apparently the first reported from the western hemisphere (J.K. Hiltunen, pers.comm.).

The most abundant elements of the nearshore benthic fauna were Nematoda, Oligochaeta, Mollusca and Chironomidae. Amphipods, Pontoporeia hoyi at 20m and mainly Hyaella azteca at shallow stations, were abundant at only a few stations in Lake Huron and North Channel. Insects other than chironomids, mainly Ephemeroptera and Trichoptera, were collected at 83% of all stations at depths of 5 and 10m and 33% of all 20m stations.

The depth and substrate preferences of the most common taxa (those found at 15 or more stations) were examined by comparing frequencies of occurrence at 3 depths and mean abundances on the various substrata. Deepwater (20m) forms found in approximately equal numbers on all substrata included Stylodrilus herringianus, Vejdovskyella intermedia, Procladius and Monodiamesa spp. Peloscolex ferox was collected most frequently at 20m and seemed to avoid gravel. Pontoporeia hoyi was most abundant on gravel, sand or silt at 20m. Stylaria lacustris and Heterotrissocladius spp. were found most frequently at 10m and 20m with the former being most abundant on rock and the latter showing no clear substrate preference.

The largest populations of Cryptochironomus, Cryptotendipes and Tanytarsus were sampled at 5m on gravel and silty sand, but each was most frequently collected at 10m. The following taxa were collected on various substrata at about equal frequencies at depths of 5m and 10m: Potamothenix vejdoskyi, Ephemera simulans, Microtendipes spp., Polypedilum scalaenum and Cladotanytarsus - gravel; H. azteca and Pseudosmittia-gp. - rock; Ablabesmyia, Pseudochironomus spp. and Piquetiella michiganensis - rock and gravel.

Caenis and Thienemannimyia - gp, were most common and abundant on rock and gravel at 5m. Other taxa which were most frequently collected at 5m either showed no clear substrate preference (e.g. Parakiefferiella) or tended to be distinctly less abundant on certain substrata (e.g. Dicrotendipes - gravel and sand, Polypedilum simulans - silt, Marstonia decepta - sand).

Potamothenix moldaviensis, Slavina appendiculata, Gyraulus parvus, Pisidium spp. and Nanocladius spp. seemed to be indifferent to both depth and substratum. Of these, only Pisidium spp. and Nanocladius spp. occurred at high densities and since each included several species which could not be separated reliably, broad distributions are not surprising.

Ordination was used in an attempt to define communities of invertebrates which could be related to environmental factors such as lake, depth or type of substratum. Data matrices used in the computations consisted of $\log_{10}$ and percentage transformed counts of the 50 most common taxa, groups of taxa (e.g. Tubificidae, Gastropoda, Chironomini, etc.) or combinations of groups and individual taxa. Both Principal Components Analysis (PCA) and Reciprocal Averaging (RA) techniques were applied; PCA consistently gave superior results in terms of the amount of variance 'explained'. Ordinations based on percentage composition reflected the relative dominance of a few groups, especially Nematoda, Tanytarsini and Gastropoda, but showed no relationship to any obvious environmental factor. Of the ordinations performed, the best results were obtained using PCA and log-transformed counts of selected taxa and groups, with the results shown in Figs. 5 & 6. The first three principal component axes account for 30, 15 and 10% of the variation in the data matrix, not a very strong ordination. Tanytarsini, P. hoyi, other Amphipoda, Nematoda, V. intermedia, S. herringianus and Chironomini were the most unique elements of the fauna (Fig. 5). Axis 1 scores in the ordination of samples (Fig. 6) mainly reflect total abundance, Axis 2 separates most stations with rock substrata from all others and Axis 3 is weakly related to depth.

It is difficult to define distinct communities from such a weak ordination; few stations had unique combinations of taxa. The most obvious group consists of stations with silty substrata at depths of 10 and 20m in North Channel (#1 in Fig. 6) characterized by P. hoyi, M. speciosa and a variety of oligochaetes, all at low densities (total standing stocks: 450-6000 individuals m^{-2}). The deepwater communities on sand and gravel in Lake Huron and open Georgian Bay (#2 in Fig. 6) were dominated by Nematoda and immature Tubificidae. These areas are more subject to wind-generated water movements as indicated by their coarser sediments. Most stations in group #3 were shallow with rocky substrata, while the remaining stations were very heterogenous including all depths and types of

substratum. These stations differed mainly in the relative and absolute abundance of Tanytarsini (especially Cladotanytarsus), Chironomini (especially Pseudochironomus), snails and amphipods. Ablabesmyia and Pseudosmittia - gp. were characteristic of most stations in group 3.

DISCUSSION

Previous assessments of the trophic status of Lake Huron, Georgian Bay and North Channel have been that the former is in the early stages of mesotrophy (Shrivistava 1974), Georgian Bay is oligotrophic (Patalas 1972) and North Channel may be somewhat enriched by organic detritus entering via the St. Mary's River (Loveridge and Cook 1976). Shrivistava's (1974) conclusions were based on apparent decreases in the abundance of the amphipod, *P. hoyi*, and increases in the abundance of oligochaetes between 1960 and 1971. As pointed out by Cook and Johnson (1974), these changes may actually have resulted from differences in the season and pattern of sample collection. The results of earlier surveys of the nearshore waters (0-25m) of Lake Huron and those of the present survey are summarized in Table 4. The only group collected in similar numbers in all studies has been the Sphaeriidae, perhaps because these are relatively large and immobile so are more reliably collected and retained by the grabs and coarse sieves (500-600µm) used in the earlier studies. The different proportions of other groups and larger total standing stocks seem to reflect the more efficient techniques used in 1980. Especially significant is the fact that all types of substrata were sampled while earlier surveys were limited to sediments which could be collected by grabs, generally sands and silts.

The importance of the techniques used to collect samples is further emphasized by comparison of the samples collected by Loveridge and Cook (1976) at depths of 10-21m in Georgian Bay with those from the same range of depths in the present survey (Table 5). Since they used a finer mesh (100µm) to concentrate their samples, Loveridge and Cook undoubtedly lost fewer animals during the sieving process. The large proportion of nematodes in their samples is good evidence of this. Since there have been no changes in Georgian Bay since 1974 which could logically account for a 500% increase in total standing stocks, I conclude that the diver-operated core and airlift are much more efficient in sampling benthic invertebrates than is the Ponar grab (see also Flannagan 1970).

The mean total benthic standing stock at depths of 10-21m reported from North Channel by Loveridge and Cook (1976) is identical to that found in the present survey (Table 5). There are, however, differences in the relative contribution by various groups, especially Sphaeriidae, P. hoyi and Chironomidae. I interpret this to mean that nematodes have been underestimated because of the coarser mesh sieves used in 1980, and the different proportions of the other groups are mainly a result of the greater range of types of substrata sampled by the divers.

Barton and Carter (1979) sampled the benthic fauna of Owen Sound near Transects 15A-C and off Wasaga Beach near Transect G6. Samples taken in August 1978, in Owen Sound with a Shipek Grab were, in most cases, qualitatively similar to those taken in 1980, but the latter samples gave standing stock estimates which were 2-5 times larger. The quantitative differences were not so great off Wasaga Beach, but this is probably because Transect G6 was not in the area enriched by organic detritus from the Nottawasaga River which was sampled in 1978. Barton and Carter (1979) found a zone of heavily enriched sediments with very large standing stocks, consisting mainly of Tubificidae, in Owen Sound south of Transect G15A. The zone of enrichment does not appear to have spread further into the bay. In fact, none of the stations sampled during 1980 showed evidence of significant organic enrichment or environmental degradation. Pollution tolerant organisms never dominated the fauna in any part of the study area.

Barton and Carter (1982) recently demonstrated that exposure to wave action is one of the most important environmental factors influencing the composition of epilithic invertebrate communities in eastern Georgian Bay. Evans and Stewart (1977) felt that frequency of disturbance of the sediments by waves had a major impact on the abundance of benthic animals at depths of 6 and 9m in Lake Michigan. On the basis of these observations, the ordination of the present series of samples was expected to show some relationship to degree of exposure.

That is, deep stations should be less exposed than shallow ones, west facing transects should be more exposed than east facing ones, etc. The results did not support this hypothesis except that shallow stations with rock substrata were generally grouped separately from those on other substrata. Since this survey was not specifically designed to investigate the role of wave action as a determinant of benthic community structure, this result is not too surprising. Barton and Carter (1982) found that there were substantial seasonal changes in their index of exposure on any given transect, and the present survey took nearly a month to complete. Autumn is also the time when most insects are present as early instars which are still in the process of dispersing to preferred habitats after hatching in very shallow water (see review by Barton 1981).

There are at least two other possible reasons for the failure to define distinctive communities in the study area and the environmental factors which control them: 1) at depths of 5.20m the direct action of surface waves may be subdominant to less easily quantifiable factors such as currents and internal waves, and 2) the fauna of the nearshore zone is extremely diverse, but has relatively few dominant species, and these have broad tolerances for depth and substrate. The sample size used in this survey may have been too small to accurately estimate differences in the abundance of subdominant, but distinctive, species.

The effects of currents and internal waves on benthic communities in lakes are poorly understood, but have been reported on a local scale by several investigators. Wind driven currents and the Coriolis effect seem to be important factors in the distribution of benthic animals in certain bays such as Saginaw Bay (Schneider et al. 1969) and Owen Sound (Barton and Carter 1979). Brinkhurst (1974) and others have suggested thermal stress associated with internal seiches as the cause of the 'sublittoral minimum' in the abundance and

variety of benthic animals. Emery (1970) reported direct observations of mortality of benthic fish and crayfish due to an internal seiche in Georgian Bay. The consistently low standing stocks observed at 20m in North Channel may represent a 'sublittoral minimum', especially in view of the relatively higher standing stocks in deeper water reported by Loveridge and Cook (1976).

Choice of an appropriate sample size is always a problem in designing benthic surveys (Elliott 1977, Green 1979). The final decision is usually a compromise between statistical adequacy and the resources available for processing the samples. The 3 replicate samples of 78.5cm used in the present survey appeared to be adequate to estimate the standing stock of the dominant species on most substrata, but more effort appears to be needed to assess less abundant species on heterogeneous substrata such as gravel and rock. This problem is by no means unique to this study; the variances of species counts at individual stations were similar to those reported from other benthic surveys (Downing 1979). The most appropriate number and size of samples from various substrata in the Great Lakes will probably have to be determined empirically.

Despite these limitations, the results of this survey indicate that the nearshore zone of Lake Huron, Georgian Bay and North Channel is a complex environment which supports a very diverse benthic fauna. The depth zone of 5.20m is the area of transition from the shallow wave-zone characterized by a basically rheophilic community (Barton and Hynes 1978) to the deep, offshore zone dominated by P. hoyi, oligochaetes and sphaeriids. This is not a sharp break, the depth ranges of various characteristic species, such as Pseudochironomus, Pseudosmittia and P. hoyi, seem to vary with local conditions. The broad substrate tolerances observed for most taxa may be highly adaptive in such a dynamic environment.

Finally, special mention should be made of the occurrence of Ripistes parasitica on Transect A in North Channel. This species was included in a recent key to the Naididae of North America by Hiltunen and Klemm (1980) since it was suspected to be present, but could not be confirmed (J.K. Hiltunen, pers. comm.). It is widely distributed in Europe and Russia where it typically occurs in association with rooted vegetation (Popchenko 1980, Juget 1980). The specimens from North Channel were found at a depth of 10m on a bottom of rock with pockets of sand and gravel up to 10cm thick. No macrophytic vegetation was apparent. A total of 13 specimens were found which gives an estimated abundance of 552 m⁻². I have also seen this species in samples from similar habitat in Thunder Bay, Lake Superior. This distribution suggests that the species has reached the Great Lakes via ships engaged in international trade.
